

10870 Recurrences

Consider recurrent functions of the following form:

$$f(n) = a_1f(n - 1) + a_2f(n - 2) + a_3f(n - 3) + \dots + a_df(n - d), \text{ for } n > d,$$

where a_1, a_2, \dots, a_d are arbitrary constants.

A famous example is the Fibonacci sequence, defined as: $f(1) = 1, f(2) = 1, f(n) = f(n - 1) + f(n - 2)$. Here $d = 2, a_1 = 1, a_2 = 1$.

Every such function is completely described by specifying d (which is called the order of recurrence), values of d coefficients: a_1, a_2, \dots, a_d , and values of $f(1), f(2), \dots, f(d)$. You'll be given these numbers, and two integers n and m . Your program's job is to compute $f(n)$ modulo m .

Input

Input file contains several test cases. Each test case begins with three integers: d, n, m , followed by two sets of d non-negative integers. The first set contains coefficients: a_1, a_2, \dots, a_d . The second set gives values of $f(1), f(2), \dots, f(d)$.

You can assume that: $1 \leq d \leq 15, 1 \leq n \leq 2^{31} - 1, 1 \leq m \leq 46340$. All numbers in the input will fit in signed 32-bit integer.

Input is terminated by line containing three zeroes instead of d, n, m . Two consecutive test cases are separated by a blank line.

Output

For each test case, print the value of $f(n) \pmod m$ on a separate line. It must be a non-negative integer, less than m .

Sample Input
